## ABSTRACT

The use of *in vitro* culture of *Hypericum* spp. as an experimental system with prospective biotechnological application was triggered by discovering of new activities of hypericin and its derivatives. At the end of the 1990s it was evident that along with anti-depressive effects of *Hypericum* extracts, there are other very important activities such as anticancer and antiviral which rate the extract and/or some of the individual constituents to the leading herbal products in the world. From among the representatives of this extensive genus, complex research, including *in vitro* culture and biotechnology, was performed only with *H. perforatum*. Besides the knowledge we have from this model *Hypericum* species, there are some partial but promising results from other species of the genus which can be considered as candidates for further investigations and possible future application. This review summarises recent knowledge on some fundamental aspects on hormonal or hormone-like regulation of plantlet differentiation of *Hypericum* species *in vitro*, morphogenetic programmes leading to organogenesis, ways of enhancing biosynthesis of profiling secondary metabolites by plant growth substances and/or elicitors and ways of small-scale production of plantlets biomass. To-date results favour differentiated tissues for further studies of biosynthesis of secondary metabolites due to presence of morphological structures serving for their accumulation although promising studies were performed with dedifferentiated cell and callus cultures as well.

**Keywords:** embryoid, plant growth substances, shoot and root development

**Abbreviations:** ADE, adenine; BAP, 6-benzylaminopurine; 2,4-D, 2,4-dichlorophenoxyacetic acid; IAA, indole-3-acetic acid; IBA, indole-3-butyric acid; 2iP, 6-( $\gamma$ ,  $\gamma$  dimethylallylamino)-purine; KIN, kinetin; NAA, naphthalene-1-acetic acid; RAPD, random amplified polymorphic DNA; TDZ, thidiazuron

## INTRODUCTION

The genus *Hypericum* is the largest in the Hypericaceae family containing more than 460 species (Robson 2006) belonging to 30 sections. The species are characterized by an extensive infraspecific and interspecific variation regarding distribution, habit, morphology, way(s) of reproduction, basic chromosome number, ploidy level and potential to synthesize bioactive substances. Some *Hypericum* species are distributed worldwide but some are endemic. The habit of the species range from small herbs to about 10 m tall trees with an extensive morphological variation. Different *Hypericum* species reveal high plasticity of reproduction and coexistence of several ways of seed formation even on individual plant (Matzk *et al.* 2001, 2003). The

basic chromosome number within the genus forms a descending series from 12 to 7 (possibly to 6) (Robson and Adams 1968). Tetraploidy has been recorded on the basic chromosome numbers  $x = 8, 9$  and  $10$  but not on  $x = 7$  or definitely on  $x = 12$ ; and higher degrees of polyploidy are associated with the largely apomictic *H. perforatum* ( $2n = 32, 48$ ) and its hybrid with *H. maculatum* ( $2n = 32, 40, 48$ ) (Robson 1981). Great variation occurs also in ability to synthesize bio-active substances; some of them, namely hypericins, are unique in the plant kingdom. It is assumed that the representatives of about 60 percent of *Hypericum* sections are able to produce these secondary metabolites (Robson 2003) which contribute to wide spectrum of pharmacological effects. Besides the use of *Hypericum* species as valuable medicinal plants, some of them are also popular

horticultural crops.

These all makes the genus a fascinating subject for biotechnological investigations. Most of the information we have on regulation of morphogenesis *in vitro* comes from *Hypericum perforatum* as a model with the initial studies in the 1990s (Čellárová *et al.* 1992; Zdunek and Alfermann 1992). As shown later, there are some other species with promising results for prospective biotechnological use (reviewed by Čellárová 2003). This review summarizes the current status of knowledge on the role of exogenous signals in morphogenesis and organogenesis in *Hypericum* spp. under *in vitro* conditions.

## EFFECT OF EXOGENOUS SIGNALS ON MORPHOGENETIC RESPONSE AND BIOSYNTHETIC POTENTIAL OF *HYPERICUM* SPP. CELLS AND TISSUES CULTURED *IN VITRO*

### Exogenous signals in shoot and root development

Phytohormones and their synthetic analogues represent the most important exogenous factors in regulation of morphogenesis *in vitro*. Cytokinins are involved in regulation of many aspects of plant development. It is evident that their resulting effect depends on many other signals, hormonal and environmental, perceived by plant cell (D'Agostino and Kieber 1999; Brault and Maldiney 1999). Cytokinins are required for proliferative shoot apical meristem activity and are known to promote outgrowth of dormant axillary buds (reviewed by Werner and Schmülling 2009). Some exogenously added cytokinins and/or their synthetic analogues were repeatedly proved to be effective in multiple shoot apical meristems development in several representatives of the genus *Hypericum*. 6-benzylaminopurine (BAP) alone in concentration ranging between  $10^{-7}$  to  $10^{-4}$  M or in combination with low auxin concentrations were effective for shoot differentiation from various explants of *H. perforatum* (Čellárová *et al.* 1992; Zdunek and Alfermann 1992; McCoy and Camper 2002; Santarém and Astarita 2003; Gadzovska *et al.* 2005; Franklin and Dias 2006; Karppinen *et al.* 2007) *H. erectum* (Yazaki and Okuda 1990), *H. canariense* (Mederos *et al.* 1997), *H. foliosum* (Moura 1998), *H. bupleuroides* (Çirak *et al.* 2007), *H. triquetrifolium* (Karakas *et al.* 2009; Namli *et al.* 2009), *H. maculatum*, *H. annulatum*, *H. tomentosum*, *H. monogynum*, *H. kalmianum* and *H. canariense* (Čellárová, unpubl.) (Fig. 1B, D, G, J, L, M). BAP or meta-topolin treatments successfully induced callus capable of regeneration and shoot differentiation in *Hypericum* sp. hybrid (Meyer *et al.* 2009). In addition to the morphogenetic role of BAP, several reports indicate that manipulation with concentration of this cytokinin in the culture medium can optimize hypericin production by shoot cultures of hypericin-producing *Hypericum* species *in vitro* (Gadzovska *et al.* 2005; Karakas *et al.* 2009). Smith *et al.* (2002) found that cytokinin supplementation of shoot culture medium resulted in a proliferation of abundant leaf glands with enhanced levels of hypericin as compared to *H. perforatum* controls. Increasing levels of BAP in *H. perforatum* shoot cultures stimulated also formation of another bioactive compound hyperforin (Charchoglyan *et al.* 2007). On the contrary, Murch *et al.* (2000) did not find BAP effective for *in vitro* regeneration of shoots from hypocotyl explants of *H. perforatum*. They developed an effective regeneration system using thidiazuron (TDZ) supplementation followed by culture on basal medium. These authors provided later the first evidence about the physiological role of mammalian neurohormones melatonin and serotonin in morphogenesis of *H. perforatum*. Increased endogenous levels of serotonin corresponded with increased rate of shoot formation and elevated endogenous levels of melatonin correlated with *de novo* root formation (Murch *et al.* 2001). High TDZ concentrations were effective not only for enhancing the number of clustering shoots in *H. perforatum* but also for hypericin and pseudohypericin production (Liu *et al.* 2007). TDZ had no positive effect on hyperforin ac-

cumulation (Table 1). For stem explants of *H. humifusum* and *H. canariense* 2iP exhibited an inductive effect on multiple shoot formation (Čellárová, unpubl.) (Fig. 1C, K).

Root formation in *in vitro* cultures occurs either spontaneously due to sufficient endogenous auxin level or can be induced by exogenously supplied culture medium with auxins or their synthetic analogues. They regulate diverse responses in plant development. Large number of auxin-regulated genes is involved in transcription regulation or RNA metabolism through a complex network (Huang *et al.* 2008). The roots in *Hypericum* species cultured *in vitro* differentiate on basal medium lacking auxins, on half-strength medium with or without auxins or under effect of exogenously added indole-3-acetic acid (IAA), indole-3-butyric acid (IBA) or naphthalene-1-acetic acid (NAA) as reported for *H. perforatum* (Čellárová and Kimáková 1999; Pasqua *et al.* 2003; Zobayed and Saxena 2003; Wojcik and Podstolski 2007; Goel *et al.* 2009), *H. bupleuroides* (Çirak *et al.* 2007) or *H. canariense* (Mederos Molina 1991) (Table 1). Exogenous supplementation of culture media with auxins or auxinoids does not always lead to root formation only. While root culture of *H. tomentosum* derived from root cuttings on MS medium with IAA promotes proliferation of adventitious roots, in other species like *H. maculatum*, *H. annulatum* or *H. pulchrum* the effect of exogenously added IAA or IBA resulted in root proliferation from which multiple shoot differentiated spontaneously without cytokinin supplementation (Čellárová, unpubl.) (Fig. 1A, E, F, H, I).

In all these experiments different plant parts were used for shoot or root differentiation and multiplication. From among the explants most of investigators favour root cuttings as the most responsive to exogenous morphogenetic signals. Franklin and Dias (2006) concluded that regeneration response in *H. perforatum* is clearly plant growth regulator-driven and explants-dependent phenomenon.

### Regulation of dedifferentiation

Most of data on isolation of callus and cell suspension cultures within the genus *Hypericum* come from *H. perforatum* and some other representatives able to synthesize valuable substances. For *H. perforatum* in most cases supplementation of media with either a balanced level of auxins and cytokinins or auxins, especially 2,4-dichlorophenoxyacetic acid (2,4-D) and NAA exceeding cytokinin content was beneficial for callus induction and proliferation (Čellárová and Kimáková 1999; Pretto and Santarem 2000; Bais *et al.* 2002; Pasqua *et al.* 2003). Surprisingly, Gadzovska *et al.* (2005) isolated friable callus from *H. perforatum* on the medium with lower concentrations of cytokinin BAP ranging between 4.4 to 8.9  $\mu$ M. These results indicate a crucial role of genotype in type of morphogenetic response within a particular species. Higher concentrations up to 22.2  $\mu$ M led to compact callus formation. These compact calli were subjected to analyses of the content of hypericin and pseudohypericin. While the content of the former remained unchanged, the latter was affected by BAP. Induction effect on callus proliferation by 2,4-D was published also for *H. brasiliense* (Cardoso and Oliveira 1996) and its combination with NAA for *H. patulum* (Ishiguro *et al.* 1999). Kartnig *et al.* (1996) reported on the isolation of callus and cell suspension cultures of seven *Hypericum* species (*H. maculatum*, *H. tomentosum*, *H. bithynicum*, *H. glandulosum*, *H. balearicum*, *H. olympicum* and *H. perforatum*) under the same culture conditions using BAP and NAA with an aim to ascertain the ability to accumulate some secondary metabolites, especially hypericin and pseudohypericin and flavonoids (Tables 1, 2). Although these findings indicate that even undifferentiated cell cultures contain hypericins which are accumulated and/or synthesized *in planta* in specialized dark gland structures, their continuous production by cell cultures where these structures are absent is questionable.

### Stimulation of biosynthetic potential of cell and tissue cultures by elicitors

The exogenous application of biotic or chemical elicitors to the cell cultures is used for enhancement of biotechnological production of secondary metabolites. The first report showing the stimulatory effect of mannan, an elicitor from yeast on hypericin production by shoot cultures of *H. perforatum* was published by Kirakosyan *et al.* (2000b). Later, Bais *et al.* (2002) examined the effect of jasmonic acid, salicylic acid and fungal cell wall elicitors from *Phytophthora cinnamoni* on production of hypericins by *H. perforatum* cell cultures. They found that only jasmonic acid stimulated growth of cells under dark conditions and increased accumulation of hypericin in the cells grown in the dark compared to elicited cell cultures grown in the light and their

respective controls. Charchoglyan *et al.* (2007) have proved that elicitation by jasmonic acid, methyl jasmonate and mannan did not trigger accumulation of hyperforin in *H. perforatum* calli but stimulated accumulation of hyperforin and secohyperforin in morphogenic cultures due to differentiation of translucent glandular structures as accumulation sites which are not present in callus cultures. Stimulating effect of methyl jasmonate and its analogue 2, 3-dihydroxypropyl jasmonate on production of hypericins and hyperforin in microshoots of *H. perforatum* and *H. sampsonii* was recorded by Liu *et al.* (2007) although the former inhibited biomass production especially in *H. perforatum*. Along with stimulating effect of methyl jasmonate on the production of hypericin and hyperforin, Pavlik *et al.* (2007) used inactivated culture of *Agrobacterium tumefaciens* which exhibited similar effect (Table 3).

**Table 1** Morphogenetic response of some *Hypericum* species on PGRs (arranged according to alphabetical order of the species).

## PATTERNS OF *IN VITRO* REGENERATION IN THE GENUS *HYPERICUM*

Regeneration of plants from *in vitro* cultured explants can proceed in two specific ways, from either unipolar or bipolar structures. Exogenous signals promoting shoot and root differentiation are described in more detail above. Here I focus mainly on somatic embryogenesis. The first note on somatic embryogenesis came from the paper of Franklin and Dias (2006) who tried to elucidate the specific pathways of regeneration in cultures originated from root explants of *H. perforatum* on culture medium supplemented with BAP and IAA. They found that regeneration can occur by both, organogenesis and somatic embryogenesis. The shoots were initiated from globular structures attached to the explants while somatic embryos developed from those detached from the explants. However, the cotyledonary embryos failed to establish root system. Later, Pasqua *et al.* (2008) obtained somatic embryos and normal shoots from leaf-derived callus as a result of separate morphogenetic programmes. While the former were obtained on medium supplemented with 2,4-D, NAA and kinetin (KIN), the latter differentiated on the medium supplemented with TDZ combined with IBA. However, the efficiency of embryos development remained very low. Early-stage embryo-like structures were observed also in callus cultures of Balkan endemic *H. rumeliacum* cultured on medium supplemented with BAP and NAA (Danova *et al.* 2010). These preliminary results indicate that some *Hypericum* species possess endogenous potential for different morphogenetic programmes but proper exogenous signals for normal embryo conversion should be uncovered.

## SMALL-SCALE CULTURE OF DIFFERENTIATED STRUCTURES IN BIOREACTORS

The use of large-scale cultures for production of uniform and high-yielding plants requires optimization of culture system for proliferation of explants followed by shoot regeneration. The first attempt to develop an optimized protocol for the *in vitro* multiplication of *H. perforatum* in bioreactor was made by Zobayed and Saxena (2003). Based on test of regeneration potential of different tissues they selected root explants for bioreactor culture which regenerated *de novo* shoots under the effect of TDZ. More than 95% of the regenerated plantlets were successfully adapted to greenhouse conditions. Similar approach for the same species was recently reported by Goel *et al.* (2009). The authors used culture of adventitious roots regenerated from shoot-derived callus on medium supplemented with IAA and IBA. Shoots proliferated from excised roots on medium supplemented with KIN which was even more efficient than BAP or TDZ. These authors assessed clonal fidelity of regenerated plants by RAPD analysis and found that more than 50% of the assessed regions were polymorphic. Taking into account that only small part of the genome is assessed by the RAPD primers, the micropropagated plants can be considered as variable. However, variability is a common feature of *H. perforatum* grown in natural habitats. The *in vitro* culture can contribute to some extent to this physiological variation. An opposite approach for *H. perforatum* was recently applied by Cui *et al.* (2010). They used adventitious roots originated from leaf explants on MS medium supplemented with IAA for culture in a balloon type bubble bioreactor. The biomass of adventitious roots which were cultured in a bioreactor under optimised culture conditions,

i.e. half strength MS medium supplemented with KIN and IBA, increased over a 5 week subculture almost 18-fold. Moreover, the roots were capable of synthesis not only flavonoids, phenolics and chlorogenic acid but also hypericin in surprisingly high amount (Table 2). An example of bioreactor culture of *H. tomentosum* adventitious roots derived from root cuttings on MS medium supplemented with IAA and further cultured in MS hormone-free medium is shown in Fig. 1N (Čellárová, unpubl.).

**FUTURE PROSPECTS**

The genus *Hypericum* is, as to the number and variability of species, very extensive. Despite that there are only few representatives that have been successfully introduced into *in vitro* culture. Almost all we know about exogenous stimuli taking part in regulation of morphogenetic responses comes from *H. perforatum* which can be considered as a model. The study of *H. perforatum* in detail including *in vitro* culture and biotechnology was triggered by significant progress in the field of a study the photodynamic activity of hypericin and its derivatives with potential use in photodynamic therapy of cancer. Along with these naphthodian-

trones, it is evident that there are other constituents such as phloroglucinols and flavonoids which contribute to the synergic effect of the *Hypericum* extract. Many of the fundamental aspects such as biosynthesis of these valuable constituents, association of the bio-active substances with unique morphological structures, genes and the respective enzymes involved in biosynthetic pathway and others remain partially or completely uncovered so far.

Introduction of other *Hypericum* species into *in vitro* culture, especially those with qualitative differences in biosynthetic potential, determination of exogenous signals needed for differentiation and/or dedifferentiation, production of biomass of plants and/or embryoids rather than cell cultures due to presence of special morphological structures for accumulation/biosynthesis of the valuable secondary metabolites seems to be essential for further progress in this area.

Search for genes coding for key enzymes of the biosynthetic pathways leading to formation of valuable compounds and knowledge on their regulation are an essential prerequisites for their potential biotechnological production. For studying the gene function and manipulating the host genome an efficient transformation system is required.

**Table 3** Stimulation of secondary metabolites synthesis in *Hypericum* species by elicitors.

| Species              | Type of elicitor  | Type of culture          | Effect on product   | Reference                      |

Those we have at present are either not sufficiently reproducible or lack regeneration capability of complete plants. Along with candidate genes involved in the pathways of bio-active substances, there is a need for prospective manipulation of apomixis genes; some *Hypericum* species may serve as a suitable host for such studies.

Despite all these limitations, there is a chance to develop tissue or cell culture systems for commercial production. Among them a continuous biomass production of high-yielding *Hypericum* spp. tissues and organs or embryoids for making artificial seeds can be taken into account. Further development of effective cryopreservation protocols for *Hypericum* spp. would be very helpful in establishment of gene bank of elite genotypes.

## CONCLUSIONS

This review attempts to summarize the results of biotechnology of *Hypericum* spp. achieved especially over the last decade. From these results it can be concluded:

- i) Despite positive achievements on regulation of morphogenesis and organogenesis in some *Hypericum* species, especially for *H. perforatum*, the number of other representatives of the genus containing valuable compounds which were successfully introduced into *in vitro* culture so far with an aim of future biotechnological production is still limited;
- ii) In general, cytokinins and cytokinin-like compounds have been proved as effective not only for shoot induction and proliferation but indirectly also for production of hypericins;
- iii) It is likely that in isolation of cell and callus cultures genotype has a decisive role; for different genotypes diverse exogenous hormone-like signals were inductive;
- iv) Elicitation as a mean of increasing secondary metabolite biosynthesis seems to be more applicable for differentiated aerial plant parts than for cell suspension cultures or calli;
- v) In *H. perforatum*, and, possibly in some other species as well, differentiation of plantlets *in vitro* can be realized either via shoot or root meristemoid or somatic embryos formation although the conditions for complete conversion of the latter into plantlets failed;
- vi) All these results are promising for their prospective use in small-scale production of plantlets in bioreactor.
